**Abstract** The aim was to report the results of deep sclerectomy (DS) with supraciliary hema implant and the influence of the surgical complications on intra-ocular pressure (IOP). Forty-eight eyes of 41 patients with open angle glaucoma (OAG), who underwent DS with supraciliary hema implant (Esnoper<sup>®</sup> V-2000), were included in this study. A significant IOP reduction was observed, changing from a preoperative mean of  $24.6 \pm 6.33$  mmHg to  $16.5 \pm 4.4$  mmHg ( $p < 0.001$ ) at 12 months and  $16.1 \pm 3.4$  mmHg ( $p < 0.001$ ), at 24 months. Similarly, a significant reduction in the number of glaucoma drugs needed was observed, varying from 2.71 to 0.22 ( $p < 0.001$ ) and 0.4 ( $p < 0.001$ ), 1 and 2 years after surgery. Goniotomy with the Nd:Yag Laser was performed in 30 eyes (62.5 %) with a mean time between the surgery and the procedure of 150 days, producing a mean IOP reduction of 4.0 mmHg ( $p < 0.001$ ). The main intra-operative complications were microperforation of the trabeculodescemet membrane (TDM) in 1 eye

(2.08 %) The main early postoperative complications were seidel at 24 h in 11 eyes (22.91 %), hyphema in 7 eyes (14.58 %), choroidal detachment in 3 eyes (6.25 %) with macular folds in 2 (4.16 %) and need for additional mitomycin injections in 2 eyes (4.16 %). All these complications were spontaneously resolved. No correlation between these complications and final IOP was found, but a significant correlation between the presence of hyphema and higher IOP 24 months postoperatively ( $p = 0.048$ ) was observed. DS with supraciliary hema implant is a safe and effective technique for the management of OAG. The presence of hyphema during the first week after the surgery could be considered as a negative prognostic factor in DS with supraciliary implantation.

**Keywords** Deep sclerectomy · Supraciliary hema implant · Hyphema

## Introduction

Deep sclerectomy (DS) is a non-penetrating procedure for the treatment of open angle glaucoma (OAG) that can be enhanced with the use of antimetabolites, such as mitomycin C (MMC) or 5-fluorouracil, as well as implants. These devices are placed to facilitate the aqueous outflow by maintaining the virtual space created after removing the deep scleral flap. There is proof of the good long-term outcomes of its

implantation in the scleral bed but there are few reports of the placement of the implant in the supraciliary space and, until now, it is not known if this produces a higher reduction in IOP than in the scleral space [1, 2]. Hyphema, bleb leakage (seidel), and goniotomy for insufficient filtration through the trabeculodescemetic membrane (TDM) are the most common complications after supraciliary and intrascleral fixation. The incidence of hyphema after classic glaucoma surgery has been widely described, but no correlation with intraocular pressure (IOP) has been found. New glaucoma surgical procedures and new devices have different types and rates of complications, with implications that have been scarcely reported in the literature.

## Materials and methods

Forty-eight eyes of 41 patients with OAG, who underwent DS with supraciliary hema implant between October 2008 and July 2010, were included in this study. All surgeries were performed by the same surgeon (JL). Table 1 shows clinical and demographic characteristics of the patients in the study. Uneventful phacoemulsification was performed in 14 eyes 6 months before the DS. All patients were over 18 years old and suffered from uncontrollable OAG, primary or secondary, under maximal tolerable medical treatment or unable to fulfill the treatment. All the patients signed the consent form approved by the Department of Ophthalmology of the Hospital Germans Trias i Pujol, Barcelona, Spain.

All surgeries were performed under peribulbar anesthesia. The surgical procedure was performed following the technique first described by Mermoud [3] with the modifications suggested by Muñoz [1] for the insertion of the implant in the supraciliary space. MMC (0.02 %) was used on all patients for 3 min and washed thoroughly with balanced salt solution (20–30 mL). The hema implant (Esnoper<sup>®</sup> V-2000, AJL Ophthalmics, Álava, Spain) was placed in a full thickness scleral pocket, made with a 45° blade for the incision and a blunt spatula, 2 mm behind the scleral spur, fixed without suturing. The superficial scleral flap was reflected back and sutured with a 10/0 nylon. Postoperative treatment consisted of topical ofloxacin 0.3 % three times daily for 1 week and prednisolone acetate 10 mg/ml six times a day that tapers over

6 weeks. Goniotomy with Nd-Yag laser (Visulas<sup>®</sup> Ophthalmic Zeiss Instruments) was performed when insufficient filtration was observed through the TDM. At the time of the goniotomy, an argon iridoplasty was performed on phakic eyes and eyes with convex peripheral iris or not very open angle.

A complete preoperative ophthalmologic examination was done in all patients, including best-corrected visual acuity (BCVA) using Snellen decimal scale, IOP measurement with Goldman tonometer, visual field analysis (Humphrey<sup>®</sup>-Ophthalmic Zeiss Instruments, Jena, Germany), corneal pachymetry (UP-1000<sup>®</sup>, Nidek, Japan) and gonioscopy. Follow-up visits were scheduled at 24 h, 1, 3, 6, 12, and 24 months after the surgery and all visits included BCVA, anterior and posterior segment examination,

tonometry and gonioscopy. Ultrasound biomicroscopy (UBM) (VuMax<sup>®</sup> 35/50 Sonomed<sup>®</sup> Lake Success—NY, USA), visual field analysis, optic nerve photography or optical coherence tomography (OCT) (Stratus 3000<sup>®</sup>, Ophthalmic Zeiss Instruments, Jena, Germany) were performed at the discretion of the investigator when glaucoma progression or complications were suspected. The use of topical antihypertensive drops and goniotomy was also recorded.

The implant used in all the surgeries was the Esnoper<sup>®</sup> V-2000 (AJL Ophthalmics-Álava, Spain). It is a non-absorbable hema (2-hydroxyethyl methacrylate) implant designed to prevent the collapse of the intrascleral lake. It can be placed in the intrascleral or in the supraciliary space during DS procedure [2].

Complications of the procedure are detailed in Table 2. Postoperative complications were classified in early or late complications, if they took place before or after 1 month. Intraoperative complications are those occurred during the surgical procedure. Eyes that needed trabeculectomy conversion during DS surgery were excluded and were not considered for analysis purposes. Goniotomy was not considered as a complication, except if it was performed before one month after the surgery, meaning an insufficient TDM dissection during surgery. Complications attributable to the goniotomy were hypotony longer than 2 weeks, iris incarceration, and bleeding, with or without hyphema formation. Complications related to the bleb were the need for additional MMC injections.

## Statistical analysis

For the descriptive analysis of the data, numerical indicators were calculated in case of quantitative

variables—mean, median, standard deviation, and range—and categorical variables were presented in absolute and relative frequencies (%). To analyze the efficacy of the treatment, in terms of IOP reduction a linear mixed model was used relating the IOP separately with each of the variables of interests, and including the variable ‘Patient’ as a random effect. Contrary to standard statistical test, these models account for the correlation of the data from the same patient. Standard tests as the *t* test or the Wilcoxon test could not be used, because they assume data are independent, which is not the case with our data. All the statistical analyses have been carried out with the statistical package R, version 2.13.1. Results of statistical tests were considered statistically significant when  $p < 0.05$  [4].

## Results

Table 3 shows the mean IOP and number of hypotensive drugs change. Postoperative mean IOP at 12 months was  $16.5 \pm 4.4$  mmHg with a reduction from preoperative value of 7.9 mmHg (32.1 %), showing statistical significance ( $p < 0.001$ ). Postoperative IOP at 24 months was  $16.1 \pm 3.4$  mmHg with a reduction from a preoperative value of 8.2 mmHg (33.7 %), showing statistical significance ( $p < 0.001$ ). The number of glaucoma medications also decreased from  $2.71 \pm 0.7$  drugs per patient preoperatively to  $0.22 \pm 0.1$  ( $p < 0.001$ ) at 12 month, and  $0.4 \pm 0.1$  ( $p < 0.001$ ) at the end of study.

Goniotomy with the Nd:Yag laser was performed in 30 eyes (62.5 %), with a mean time between the surgery and the procedure of 150 days, producing a mean IOP reduction of 4.0 mmHg ( $p < 0.001$ ). Argon iridoplasty was performed in 7 eyes (23.3 %). Four

eyes (13.3 %) had a small bleeding after goniotomy without hyphema formation, 1 hypotony (3.3 %) and 1 partial iris incarceration (3.3 %) in the TDM. Preoperative BCVA in Snellen decimal chart was  $0.6 \pm 0.3$  and postoperative BCVA, 12 and 24 months after the surgery, were  $0.6 \pm 0.2$  and  $0.7 \pm 0.2$ , respectively. All the complications are summarized in Table 2. The only intraoperative complication was the microperforation of the TDM in 1 eye (2.08 %). The main early postoperative complication was seidel at 24 h in 11 eyes (22.91 %) without flat anterior chamber, spontaneously resolved 72 h after surgery in all cases except in 2 cases (4.16 %) that needed resuturing four days after surgery. Hyphema was observed in 7 eyes (14.58 %), choroidal detachment in 3 eyes (6.25 %) and additional MMC injections were necessary in 2 eyes (4.16 %) (Table 4). The presence of hyphema during the postoperative period was further analyzed. 12 months after the surgery ( $n = 48$ ), mean IOP was  $19.3 \pm 4.3$  mmHg in the 7 eyes with hyphema and  $16 \pm 4.4$  mmHg in eyes without (41 eyes). Twenty-four months after the surgery, mean IOP was  $18 \pm 2.8$  mmHg in the hyphema group (6 eyes) and  $15.6 \pm 3.5$  mmHg in eyes without hyphema (27 eyes) (Figs. 1, 2). No correlation between hyphema and final IOP was found at 12 months ( $p = 0.111$ ) but a significant correlation was observed 24 months postoperatively ( $p = 0.048$ ).

## Discussion

Most of the published studies about DS are using intrascleral implants or no implants. Only the study by Muñoz et al. [1] reports the results with a supraciliary implant (TFlux<sup>®</sup>) in isolated DS and the study by Bonilla et al. [2] with the use of supraciliary Esnoper<sup>®</sup> in combined DS and phacoemulsification. Our results are comparable to the results published by Muñoz et al. [1], although postoperative IOP in our patients

is higher ( $16.5 \pm 4.7$  mmHg compared to  $14.0 \pm 3.0$  mmHg) and postoperative hypotensive medications per patient are lower (0.2 compared to 0.3). There are no studies published in the literature with 2 years follow-up and, therefore, we cannot compare our results. The rest of the existing bibliography on DS only refers to intrascleral implants or surgeries without implants. Cheng [5] compares different series with different intrascleral implants with or without MMC, confirming that the use of implants and antimetabolites is essential to improve the results of the surgery. But it is still not clear if placing an implant in the supraciliary space produces a higher reduction in IOP than in the scleral space, or a different rate of complications.

Non-penetrating surgery with supraciliary implant fixation seems to have fewer postoperative complications than intrascleral implantation. The learning curve is short for a surgeon with expertise in glaucoma surgery and it can be achieved without major complications. At the moment, though, there are no studies comparing both techniques in term of results and complications. The incidence and management of intraoperative microperforations are similar in both techniques [1, 2]. The implantation of the Esnoper<sup>®</sup> V-2000 in the supraciliary space has been performed without complications in all the cases, and we agree with Muñoz et al. [1] that avoiding maneuvers of

**Fig. 1** Box plot eyes with/without hyphema at 12 months

**Fig. 2** Box plot eyes with/without hyphema at 24 months

suture is an additional advantage to this technique. Early postoperative complications have been similar to those described in the literature with intrascleral implant. Postoperative seidel without flat anterior chamber at 24 h was observed in 11 cases (22.9 %). Seidel incidence according to different authors is between 7 and 14 % in penetrating and non-penetrating procedures, but a completely different meaning. In non-penetrating surgery, when the anterior chamber is not shallow or flat, it can be managed with a contact lens or steroid therapy discontinuation. Although seidel is not so dangerous in non-penetrating surgeries, avoiding it undoubtedly facilitates the long-term maintenance of the subconjunctival space.

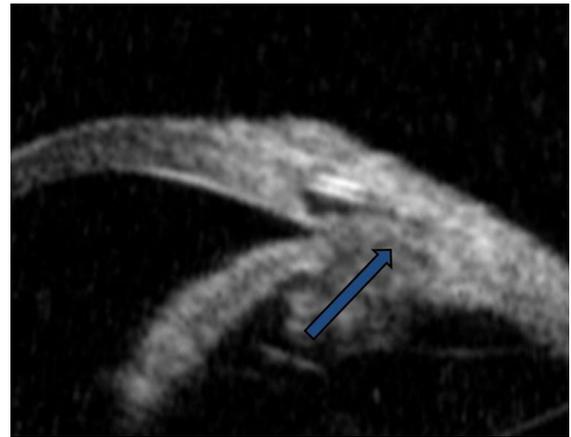

Hyphema also appears in a variable percentage in the different studies published, ranging from 0.8 [6] to 22.7 % [7] when the implant is intrascleral, and in 6.6 % when the implant is supraciliary [1]. Hyphema is more common after trabeculectomy [8] and canaloplasty [9], where it is considered to be a positive factor. Nevertheless, the interpretation of the hyphema in non-penetrating surgery is different. For Grieshaber [9] it is a sign of the reestablishment of the functionality of Schlemm's canal after canaloplasty, whereas Koch [10] holds that hyphema may appear in any surgery that produces postoperative ocular hypotension. Hamel [11] finds that the incidence of hyphema is higher in myopic eyes (19 %), but we could not find such differences. In our series, it has appeared in 7 out of 48 eyes (14.58 %) and in all cases has been lower than 1.5 mm. The origin may be an inverse reflux from the intrascleral lake to the anterior chamber through the TDM, due to the hypotension. Konstas [12] postulated that the vascular components of the sclera and ciliary body were the most likely sources of blood after trabeculectomy. When we compared the IOP, 24 h after the surgery, in eyes with and without hyphema, there was no difference between the groups, being the mean IOP of 7.8 mmHg in both, but at 12 and 24 months the eyes which had hyphema showed a significantly higher IOP. We found a non-significant correlation between the presence of hyphema and high IOP at 12 months ( $p = 0.111$ ) that became significant at 24 months ( $p = 0.048$ ). Our hypothesis is that the fibrotic and inflammatory stimulation caused by the blood has a negative effect on the long-term IOP control. It is paradoxical that hyphema, that means postoperative ocular hypotension 24 h after surgery, may have a poor prognostic factor in the longer term. We could not find any reference in the literature about the relationship between the presence of hyphema and bleb failure in DS. Cobb et al. [13] reported a significant association between aspirin intake and a higher risk of hyphema, in trabeculectomy patients, but this did not significantly affect IOP control at 2 years. Probably, TDM in non-penetrating surgery is more vulnerable to fibrosis than trabeculectomy, even after goniopuncture.

The appearance of a choroidal detachment (CD) in DS surgery has been described between 2 and 5 % of the cases, according to different series. Although the surgery with supraciliary implantation could potentially increase the incidence of this complication,

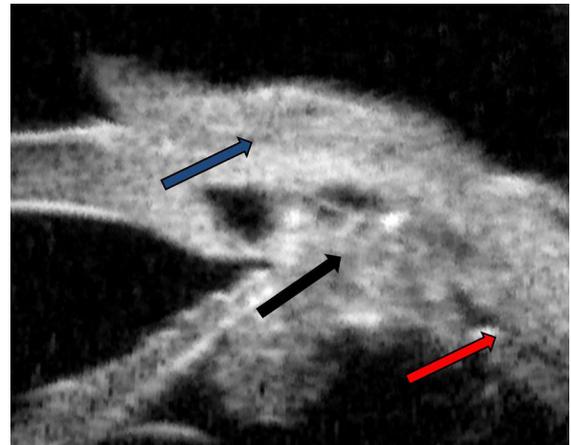

neither the series of Muñoz et al. [1] with T-Flux<sup>®</sup> nor ours points in this direction. In our study, CD occurred in 3 eyes (6.25 %). Two of the three cases corresponded to the same patient, a 48-year-old male with pigmentary glaucoma and high preoperative IOP (40 and 42 mmHg, respectively). Both eyes presented with macular folds secondary to hypotony that spontaneously resolved 1 month after the surgery. Young myopic patients are more prone to suffer from hypotony after DS with supraciliary implantation.

Uveal prolapse into the intrascleral lake is a complication scarcely described in the literature and only when intrascleral implants are used [14], probably because it is an UBM diagnosis. In our series, we have found two cases (4.16 %). The first one, a 72-year-old phakic male, was detected 5 months after the surgery. An absence of the hyporeflective suprachoroidal space and the conjunctival bleb was observed on the UBM examination (Fig. 3). IOP was 14 mmHg without topical treatment. The second case was a 60-year-old phakic patient with a complete intraoperative scleral perforation in one of the lateral incisions. Twenty-four months after the surgery, UBM exploration showed a uveal prolapse with good location of the implant and presence of the hyporeflective suprachoroidal space (Fig. 4). The bleb was present and the IOP was 16 mmHg without treatment. Uveal prolapse may not be uncommon especially with very deep procedures. Therefore, intrascleral needling should be performed very carefully.

There are no published studies comparing the complications of DS surgery placing the implant in the intrascleral or in the supraciliary space. It is not clear whether hyphema may be more frequent when the implant is placed in any of the two spaces. Blood is a widely accepted mediator of inflammation, and it is also known that scarring can lead to the failure of glaucoma surgery. When hyphema occurs after DS, blood can migrate from the anterior chamber to the subconjunctival space stimulating fibrosis of the TDM and fibroblast proliferation, resulting in a late bleb failure. It is still not clear if this is more common in the supraciliary implantation, but bleeding may be favored by subtle movements of the implant when it is not completely fixed. This could induce late fibrotic phenomenon of the TDM or even forward displacement of the implant with limitation to the aqueous filtration across the TDM. Hyphema will probably be less frequent with the new implant model, that has two lateral notches specially designed for non-stitching

**Fig. 3** Ultrasound biomicroscopy: Uveal prolapse (*Blue arrow*). Absence of hyporeflective suprachoroidal space and conjunctival bleb

**Fig. 4** Ultrasound biomicroscopy: Uveal prolapse (*Black arrow*) with good location of the implant, presence of hyporeflective suprachoroidal space (*Red arrow*) and conjunctival bleb (*Blue arrow*)

supraciliary technique. Even that placing the implant in the supraciliary space could enhance the uveoscleral outflow it could be that when the implant is located into the supraciliary space the volume of the intrascleral lake could be reduced leading to less IOP reduction [1].

## Conclusion

The insertion of the implant in the supraciliary space is an effective and safe surgery for patients with OAG

but it is still not clear if placing an implant in the supraciliary space produces a higher reduction in IOP than in the scleral space. Further studies are needed with a larger sample size comparing different implants and both techniques in terms of results and complications. It is not clear whether hyphema may be more frequent when the implant is placed in any of the two spaces but their appearance might be related to the long-term IOP results.
